 African Americans

## ABSTRACT

Alzheimer's disease (AD) pathology disrupts functional brain connectivity long before symptoms emerge. African Americans face elevated AD risk, yet underlying mechanisms remain unclear. Genetic risk differs by ancestry: *APOE-ε4* strongly predicts late-onset AD in European ancestry, whereas *ABCA7* rs115550680 confers substantial risk in African ancestry. Yet, how these variants influence neural function in African Americans is unclear. The medial temporal lobe (MTL) is an early target of AD pathology and resting-state functional Magnetic Resonance Imaging (rs-fMRI) measures of dynamic network connectivity (hereafter “flexibility”), the brain's capacity to dynamically reconfigure connectivity, provide a sensitive metric of network adaptability, potentially preceding structural decline. However, comparative influence of *APOE-ε4* and *ABCA7* rs115550680 on MTL flexibility and subregional volumes in this population is unknown. 146 older African Americans ( $Mean_{Age}=69.71$   $Mean_{SD}=6.29$ ) were genotyped for *APOE-ε4* and *ABCA7* rs115550680 via saliva samples. Rs-fMRI was used to calculate MTL flexibility and T1-weighted MRI quantified MTL subregional volumes. ANCOVAs controlled for age, sex, and education, and *APOE-ε4* when *ABCA7* rs115550680 was the predictor. *ABCA7* rs115550680 risk allele carriers exhibited lower MTL flexibility than non-carriers ( $p = .042$ ) and *APOE-ε4* allele carriers ( $p = .030$ ). They also showed hypertrophy in left anterior hippocampus ( $p = .049$ ), bilateral entorhinal cortex (ERC) (right  $p = .048$ ; left  $p = .020$ ) compared to non-carriers, and greater left ERC volume than *APOE-ε4* allele carriers ( $p = .027$ ). *APOE-ε4* or interaction effects were not significant ( $p > .05$ ). These findings provide preliminary evidence that *ABCA7* rs115550680 risk allele, but not *APOE-ε4* allele, is linked to reduced MTL flexibility and subregional hypertrophy in older African Americans, suggesting ancestry-specific mechanisms of early AD risk.

## 1. Background

Older African Americans experience disproportionately high rates of

Alzheimer's disease (AD) compared to other racial and ethnic groups in the United States (Barnes, 2022). The prevalence of AD is almost twice as high in this population, yet the neural and genetic mechanisms

underlying early vulnerability remain understudied (Mayeda et al., 2016).

The medial temporal lobe (MTL), comprising memory-critical structures such as the hippocampus, entorhinal cortex, and perirhinal cortex, is among the earliest affected regions in AD (Berron et al., 2020). Although resting-state functional Magnetic Resonance Imaging (rs-fMRI) has provided key insights into large-scale brain network alterations in AD, static connectivity approaches overlook the brain's capacity for dynamic reconfiguration over short time periods (Hutchison et al., 2013). Dynamic functional connectivity, the brain's capacity to dynamically reconfigure connectivity (hereafter "flexibility"), quantifies transient shifts in connectivity states and is emerging as a sensitive marker of early neural dysfunction (McLaren et al., 2014). In the MTL, subtle disruptions in dynamic flexibility may reflect synaptic inefficiencies and early compensatory breakdowns that occur before structural atrophy (Dickerson and Sperling, 2008). Regional hyperactivity, inter-network hypo-connectivity, and instability in the MTL, have also been linked to impaired neuroplasticity and cognitive function (Dickerson et al., 2009; Dickerson and Sperling, 2008).

Genetic factors are a major contributor to AD, accounting for an estimated 58–79 % of disease risk at the population level (Mayeux, 2006). In African ancestry, two key genetic contributors to the late-onset AD are apolipoprotein E (APOE) and ATP-binding cassette subfamily A member 7 (ABCA7) (Stepler et al., 2022). While APOE- $\epsilon 4$  allele is prevalent in this population, its associated risk is attenuated compared to European or Asian ancestry (Rajabli et al., 2018). The APOE- $\epsilon 4$  allele is also associated with hippocampal hyperactivation in older African Americans (Sinha et al., 2018). On the other hand, ABCA7 rs115550680 contributes to AD through the suppression of microglial A $\beta$  clearance and is associated with AD development in African Americans (Aikawa et al., 2018; Stepler et al., 2022). The mechanistic underpinnings of ABCA7-related AD vulnerability still remain unclear, but prior evidence implicates its role in lipid metabolism, amyloid processing, and microglial function, all of which contribute to AD pathophysiology (Miao et al., 2023). Our prior work showed that ABCA7 rs115550680 risk allele carriers had a functionally segregated entorhinal cortex and impaired learning, pointing to MTL network dysfunction as a potential early biomarker among older African Americans (Sinha et al., 2019).

The ABCA7 rs115550680 risk allele exerts a stronger association with AD risk than the APOE- $\epsilon 4$  allele in African Americans (De Roeck et al., 2019; Reitz et al., 2013; Stepler et al., 2022). We hypothesized that "Cognitively unimpaired older African Americans carrying the ABCA7 rs115550680 risk alleles will exhibit reduced MTL flexibility and subregional hypertrophy compared to both non-carriers as well as to APOE- $\epsilon 4$  allele carriers, reflecting early neural dysfunction associated with preclinical AD". The present study investigated the impact of APOE- $\epsilon 4$  allele and ABCA7 rs115550680 risk allele on flexibility and volume within the MTL region among cognitively unimpaired older African Americans. These findings aim to provide insights into ancestry-specific AD vulnerabilities which may inform future personalized-medicine targeted early intervention strategies.

## 2. Methods

### 2.1. Participants

Participants were recruited from an ongoing longitudinal study at Rutgers University–Newark of aging and AD risk in African Americans. Recruitment utilized the *Aging & Brain Health Alliance*, a university-community partnership engaging local senior centers, public and subsidized housing associations, religious institutions, health and wellness organizations, and other entities focused on the well-being of greater Newark residents. Recruitment through community-based outreach may preferentially attract individuals who are more health-engaged or who have personal or family concerns about cognitive aging, which may influence sample composition. All participants were distinct, unrelated

individuals, and no relatives were included in the study.

Participants aged 60 years or older with a Mini-Mental State Examination (MMSE) score of 24 or above were eligible for inclusion for the current study. African American race/ethnicity was determined by participant self-report at enrollment. Exclusion criteria included any diagnosis of neurodegenerative disease, use of medications typically prescribed for dementia, history of learning disabilities, self-reported alcohol and/or drug abuse, general anesthesia within the past three months, MRI contraindications, and/or refusal to provide a saliva and/or blood sample. The study was approved by the Rutgers University Institutional Review Board, adhering to ethical guidelines and regulations of the Declaration of Helsinki.

### 2.2. Procedure

Potential participants received a telephone screening to assess initial eligibility. Those who met the criteria proceeded to provide informed consent. Subsequently, participants underwent a comprehensive laboratory visit including cognitive assessments, saliva collection, and MRI scans. All imaging and clinical data, including MRI and MMSE, were collected during the same study visit, and participant age in years reflects age at that visit.

### 2.3. Measures

#### 2.3.1. Genetic procedures

Saliva samples for DNA extraction and genotyping were collected using DNA Genotek® Oragene (ORG-600) kits. These saliva sample tubes were securely stored in the laboratory before being processed for data analyses. Biosafety-trained research staff transported the samples to an off-site biotechnology facility for genotyping. The genotyping process involved quantitative PCR on Eppendorf Master cyclers using the TaqMan custom genotyping assay. Following genotyping, participants were classified as either APOE- $\epsilon 4$  allele carriers or non-carriers, regardless of hetero- or homozygosity (Foster et al., 2017). All APOE- $\epsilon 4$  allele heterozygotes were included in the study, even those with  $\epsilon 2/\epsilon 4$  genotype, as the presence of the  $\epsilon 4$  allele alone confers an increased risk for AD (Liu et al., 2013). ABCA7 rs115550680 genotyping was performed using a quantitative polymerase chain reaction, identifying "G" allele carriers as ABCA7 rs115550680 risk allele carriers (De Roeck et al., 2019). Genotyping was limited to selected candidate loci using TaqMan assays; genome-wide genotype data were not available.

#### 2.3.2. MRI data acquisition

Participants underwent MRI at the Rutgers University Brain Imaging Center (RUBIC) located at the Rutgers University–Newark campus. MRI acquisitions were conducted through 3 T Siemens TRIO scanner equipped with a 32-channel multiband parallel encoding coil. Structural scans were performed with high-resolution 3D magnetization-prepared rapid gradient echo (MP-RAGE) in the sagittal plane (TR=1900ms, TE=2.52ms, 1.0 × 1.0 × 1.2 mm voxels). The scanning parameters for the high-resolution multiband echo-planar functional imaging (rs-fMRI) were as follows: TR= 664ms, 1.8 mm isotropic voxels, 812 time points, multiband factor= 5. Total acquisition time was ~14 min.

#### 2.3.3. Resting state fMRI data analysis

**2.3.3.1. Preprocessing.** All neuroimaging data were processed and analyzed using AFNI (Linux) with standard afni\_proc.py pipeline (Cox, 1996). Rs-fMRI data underwent despiking (3dDespike), slice timing correction (3dtshift), and alignment to skull-stripped MP-RAGE images (align\_epi\_anat.py). Motion was corrected (3dvolreg), and data were smoothed to 2 mm FWHM (3dmerge). A brain mask (3dautomask) excluded non-brain voxels. A custom script was implemented to ensure data integrity by excluding trials exhibiting motion exceeding 0.3 mm

from the time series, enhancing the reliability of the analyses. To reduce noise, ANATICOR was applied (Power et al., 2014). Nuisance regressors (six motion parameters and linear drift) were modeled with 3dDeconvolve. Structural scans were normalized via Advanced Normalization Tools (ANTs) employed a diffeomorphic nonlinear registration algorithm (SyN) to a custom 0.65 mm isotropic in-house template (Avants et al., 2008; Klein et al., 2009); aligned functional data were transformed to this template for group-level analysis.

**2.3.3.2. Dynamic network construction.** Dynamic functional connectivity within the MTL was investigated, focusing on cortical and hippocampal sub-regions (subiculum, Cornu Ammonis 1 (CA1), and Dentate Gyrus (DG)/CA3) as well as Perirhinal Cortex (PRC), Parahippocampal Cortex (PHC), Posteromedial Entorhinal Cortex (pMEC), and Anterolateral Entorhinal Cortex (aLEC). The PRC and PHC provide input respectively to the lateral and medial EC, which in turn project into the hippocampus. In this study, pMEC and aLEC were considered as separate ROIs within the MTL network. For each ROI (3dmaskave), an average time series encompassing 812 time points was extracted, excluding the initial six and last six time points. These time series were subsequently divided into sub-blocks of 50-time points (33 s) to evaluate the dynamic connectivity between ROIs across 16 time-windows. The duration of the time window was set to be long enough to allow for an accurate assessment of correlations throughout frequencies located in the wavelet band of interest (0.06–0.12 Hz), but short enough to allow for a fine-grained measurement of temporal evolution over the whole session (Telesford et al., 2016). For each of the 16 non-overlapping sub-blocks, connectivity was then determined as the magnitude squared spectral coherence between each pair of ROIs to quantify modularity across time frames (Bassett et al., 2013a, 2013b, 2011). Subject-specific  $7 \times 7 \times 16$  connectivity matrices were constructed, representing coherence values ranging from 0 to 1 across 7 ROIs and 16 time-windows. Coherence, a measure of frequency-specific linear correlations between time series, was employed due to its efficacy in capturing functional relationships within the fMRI data (Sun et al., 2004). A multilayer network technique was employed, where each layer consists of a network derived from a single time window and subsequent layers correspond to subsequent time windows. This approach enabled the investigation of changes in functional brain network architecture over time. Each participant's multilayer networks were constructed by connecting nodes in the connectivity matrix to the equivalent node in the connectivity matrix of consecutive time windows. Networks were interconnected across time as a result of the multilayer network linking each network node to itself in previous and subsequent time slices. As a result of this representation, a time-dependent network was constructed that allows each network layer to be divided into densely interconnected sub-groups, called communities or modules, whose identities are reliably recorded over time frames (Bassett et al., 2013b; Mucha et al., 2010a).

**2.3.3.3. Dynamic community detection.** A Louvain-like locally greedy community detection algorithm for optimizing multilayer modularity was utilized to partition each multilayer network into temporally connected modules (Mucha et al., 2010b). A community assignment representing the module connectedness for each node and time frame was constructed by optimizing multilayer modularity. The flexibility of each node was defined as the extent to which it altered its module allegiance over the set of time frames represented by the multilayer network to enable it to measure alterations in the composition of communities through time (Bassett et al., 2013a, 2013b, 2011). Therefore, flexibility was calculated for each of our 7 ROIs (PRC, PHC, pMEC, aLEC, subiculum, CA1, DG/CA3) as the number of times a node indicated a change in community assignment, normalized by the total number of possible changes. The mean flexibility over all nodes was then computed to determine MTL dynamic network flexibility as the primary outcome. Overview of the rs-fMRI data preprocessing and dynamic network

connectivity (“flexibility”) analysis process was shown in Fig. 1a.

#### 2.3.4. MTL subregional and anterior/posterior hippocampus segmentation and volume normalization

MTL subregions and anterior/posterior hippocampus were segmented using the Automatic Segmentation of Hippocampal Subfields (ASHS) toolbox (Xie et al., 2016), which uses high-resolution T1-weighted structural MRI with multi-atlas label fusion to delineate distinct MTL structures. Segmented regions included the anterior and posterior hippocampus, ERC, Brodmann areas 35 and 36 (BA 35 and BA 36), and the PHC, bilaterally. To adjust for individual differences in head size, regional volumes were normalized to estimated total intracranial volume (eTIV) derived from FreeSurfer7.3.2 (Buckner et al., 2004; Fischl, 2012), using each participant's T1-weighted image. A representative example of the ASHS segmentation outputs is shown in Fig. 1b, illustrating the 3D reconstructions and coronal/sagittal overlays of the hippocampal and surrounding MTL subregions.

#### 2.4. Statistical analysis

Jamovi version 2.6.24.0 was used for statistical analysis. Summary statistics and histograms were generated to evaluate data distributions, and outliers were checked. Statistical approaches that allow inclusion of cases with missing data were applied to maximize available information. No data were imputed; missing values were handled using model-wise exclusion such that participants were included in all analyses for which complete data were available. A series of general linear models (ANCOVAs) was conducted to examine group differences in the MTL flexibility and subregion volumes for

- 1) *ABCA7 rs115550680* risk allele carriers and non-carriers;
- 2) *APOE-ε4* allele carriers and non-carriers; and
- 3) Direct comparison of *ABCA7 rs115550680* risk allele-only carriers and *APOE-ε4* allele-only carriers (excluding dual carriers).

All models included age, sex, and education as covariates; when *ABCA7 rs115550680* was the predictor, *APOE-ε4* status was additionally included as a covariate (and vice versa). *APOE* genotype was coded dichotomously as  $\epsilon 4$  carrier versus non-carriers, with individuals carrying at least one  $\epsilon 4$  allele ( $\epsilon 2/\epsilon 4$ ,  $\epsilon 3/\epsilon 4$ , or  $\epsilon 4/\epsilon 4$ ) classified as *APOE-ε4* allele carriers and all other genotypes classified as non-carriers. Critically, we also run two-way ANCOVA with factors *ABCA7 rs115550680* (risk allele carriers vs non-carriers)  $\times$  *APOE-ε4* (allele carriers vs non-carriers) to test interaction effects on each outcome (covariates: age, sex, and education). MMSE was not included as a covariate because all participants were cognitively unimpaired, MMSE scores showed limited variability, and MMSE did not differ across genetic groups. Volumes were normalized to eTIV; therefore, eTIV was not added as a covariate. Results are reported as F, p, and partial  $\eta^2$  ( $\eta_p^2$ ) with  $\alpha = .05$  (two-tailed). The significance value was accepted as  $p < .05$ .

### 3. Results

Demographics of the 146 participants (110 women) are shown in Table 1. Participants were between 60 and 90 years of age and on average had completed an associate degree or some college coursework. All participants were cognitively unimpaired. While 15.8 % of the participants were *ABCA7 rs115550680* risk allele carriers, 43.8 % of them were *APOE-ε4* allele carriers. Of 23 *ABCA7 rs115550680* risk allele carriers, 9 (39 %) were also *APOE-ε4* allele carriers; among *ABCA7 rs115550680* non-carriers ( $n = 123$ ), 55 were *APOE-ε4* allele carriers and 68 were non-carriers. The joint distribution of *ABCA7 rs115550680* and *APOE-ε4* carrier status is shown in Supplementary Table 1. Demographic and clinical characteristics, including age, sex, education, and MMSE, did not differ significantly across genetic groups (Supplementary Table 1).

**Fig. 1.** a) Overview of rs-fMRI Preprocessing and Dynamic Network Analysis Pipeline. This diagram illustrates the fMRI preprocessing steps and dynamic functional connectivity analysis workflow. Steps include anatomical registration, motion correction, signal regression, and transformation to template space using ANTs. Dynamic connectivity was estimated across 16-time windows using coherence and multilayer modularity. Flexibility was computed from changes in community structure over time across seven medial temporal lobe (MTL) regions of interest. Abbreviations: ANTs = Advanced Normalization Tools; MTL = medial temporal lobe. b) Segmentation of Hippocampal Subfields and Medial Temporal Lobe Subregions. Example segmentation of MTL subregions using ASHS. Coronal and sagittal views show bilateral delineation of the entorhinal cortex, parahippocampal cortex, and hippocampal subfields (including anterior and posterior hippocampus, Brodmann areas 35 and 36). The bottom left panel displays a 3D rendering of the segmented MTL structures. Abbreviations: ASHS = Automatic Segmentation of Hippocampal Subfields; MTL = medial temporal lobe.

**3.1. Main and interaction effects of ABCA7 rs115550680 and APOE-ε4 genotype**

ABCA7 rs115550680 risk allele carriers exhibited significantly lower MTL flexibility compared to non-carriers ( $F_{(1,140)} = 4.200, \eta^2 = .029,$

$p = .042$ ) with an observed power of 0.530 (Fig. 2a). There was no statistically significant impact of APOE-ε4 allele on MTL flexibility ( $F_{(1,141)} = 2.043, \eta^2 = .014, p = .155$ ) with an observed power of 0.295. ABCA7 rs115550680 risk allele carriers demonstrated significant hypertrophy in left anterior hippocampus ( $F_{(1,140)} = 3.934, \eta^2 = .027, p = .049$ ), left ERC ( $F_{(1,140)} = 5.500, \eta^2 = .037, p = .020$ ), right ERC ( $F_{(1,140)} = 3.981, \eta^2 = .026, p = .048$ ), and marginal difference in right anterior hippocampus ( $F_{(1,140)} = 3.808, \eta^2 = .026, p = .053$ ) compared to non-carriers (Table 2). There was no difference in the MTL subregional volumes between APOE-ε4 allele carriers and non-carriers ( $p > .05$ ). Across outcomes, the ABCA7 rs115550680 × APOE-ε4 interaction was not significant for MTL flexibility or MTL subregional volumes (all  $p > .05$ ). (Supplementary Table 3).

**3.2. Difference between ABCA7 rs115550680 risk allele-only and APOE-ε4 allele-only carriers**

Of 23 ABCA7 rs115550680 risk allele carriers, 9 (39 %) also carried APOE-ε4 allele and were excluded from the direct comparisons. Among ABCA7 rs115550680 non-carriers (n = 123), 55 were APOE-ε4 allele carriers and 68 were non-carriers. Direct comparisons therefore focused on ABCA7 rs115550680 risk allele-only carriers versus APOE-ε4 allele-only carriers, excluding individuals carrying both risk alleles.

ABCA7 rs115550680 risk allele-only carriers demonstrated significantly lower MTL flexibility ( $F_{(1,64)} = 4.924, \eta^2 = .069, p = .030$ ) with an observed power of 0.590 than APOE-ε4 allele-only carriers (Fig. 2b). ABCA7 rs115550680 risk allele-only carriers showed significant hypertrophy in left ERC compared to APOE-ε4 allele-only carriers ( $F_{(1,64)} = 5.137, \eta^2 = .072, p = .027$ ) (Table 3).

**4. Discussion**

In this study, ABCA7 rs115550680 risk allele carriers exhibited significantly reduced MTL flexibility compared to both non-carriers and APOE-ε4 allele carriers. They also showed hypertrophy in the left anterior hippocampus and bilateral ERC. Taken together, these findings suggest preliminary evidence that ABCA7 rs115550680 risk allele may uniquely capture early MTL network dysfunction in older African Americans. The observed subregional volumes could reflect transient, possibly compensatory or inflammatory, remodeling in MTL subregions rather than stable structural change. Overall, these findings support that

**Fig. 2.** a) Reduced Medial Temporal Lobe Flexibility in *ABCA7 rs115550680* Risk Allele Carriers. Violin plots show the distribution of MTL dynamic network flexibility values for *ABCA7 rs115550680* risk allele carriers (AG, GG) and non-carriers (AA). Each plot illustrates the full range, kernel density estimate, and median (horizontal line) within each group. Group comparisons were adjusted for age, sex, and education. Abbreviation: MTL = medial temporal lobe. b) *ABCA7 rs115550680* Risk Allele Carriers Show Lower MTL Flexibility than *APOE-ε4* Allele Carriers. Violin plots compare MTL dynamic network flexibility between individuals with only the *ABCA7 rs115550680* risk allele-only (N = 14) and those carrying *APOE-ε4* allele-only (N = 55). Each plot shows the distribution, kernel density, and median flexibility values. Statistical models were adjusted for age, sex, and education. Abbreviations: MTL = medial temporal lobe; APOE = apolipoprotein E.

MTL flexibility may reflect early neural alterations associated with AD risk among older African Americans.

Neuroimaging plays a pivotal role in detecting early AD-related brain changes. The MTL, including the hippocampus and ERC, is among the

earliest regions affected, often before cognitive symptoms emerge. Functional connectivity disruptions, particularly hyperconnectivity in MTL, has been reported in early AD (Nakamura et al., 2017) and may precede structural atrophy (Das et al., 2013; Duchateau et al., 2024).

Our study builds on this by leveraging dynamic flexibility, a more sensitive measure of neural dysfunction compared to static approaches (Hutchison et al., 2013). Altered MTL flexibility may reflect synaptic inefficiencies and early network breakdowns (Sperling et al., 2010).

Our results show that carriers of the *ABCA7 rs115550680* risk allele exhibited significantly reduced dynamic network flexibility within the MTL region compared with non-carriers. This finding is particularly relevant given that *ABCA7* is involved in lipid metabolism, amyloid processing, and microglial function, all of which are implicated in AD pathophysiology (Aikawa et al., 2018; Dib et al., 2021; Duchateau et al., 2024). The *ABCA7 rs115550680* risk allele, which is associated with impaired *Aβ* clearance and defective microglial response, may lead to early disruptions in MTL network dynamics, thereby compromising the brain's ability to engage in efficient communication across networks. These findings highlight the utility of dynamic network flexibility as a sensitive biomarker capable of detecting subtle genetic effects on MTL function.

Notably, we also observed subregional hypertrophy—an increase in tissue volume due to enlargement of cellular components—in *ABCA7 rs115550680* risk allele carriers, including the left anterior hippocampus and bilateral ERC, compared to non-carriers. Such hypertrophy may represent a transient, possibly compensatory or inflammatory response, consistent with prior reports linking astrocytic reactivity to early volumetric expansion before subsequent atrophy. These results are consistent with earlier studies that suggest *ABCA7* plays a more significant role in AD risk among individuals of African ancestry although not in those of primarily European ancestry (Berg et al., 2019; Reitz et al., 2013; Sinha et al., 2019; Stepler et al., 2022). Given that the *ABCA7 rs115550680* risk allele has been linked in our own prior studies to a functionally segregated ERC, this dysfunction may manifest as deficits in prior learning, as we observed in our cohort (Berg et al., 2019; De Roeck et al., 2019; Sinha et al., 2019; Stepler et al., 2022). Although our structural analyses were limited to anterior/posterior hippocampal divisions, the expression of *ABCA7* in the CA1 region raises the possibility that subfield-specific vulnerability may underlie some of the observed network alteration (Rosenthal and Kamboh, 2014). Understanding whether these structural alterations represent compensatory resilience or a precursor to decline will be critical for developing

ancestry-informed biomarkers of AD risk.

Functional alterations in MTL flexibility may reflect early neural alterations associated with AD risk among older African Americans, possibly preceding detectable atrophy in some regions while co-occurring with compensatory-driven expansion in others. In contrast, the *APOE-ε4* allele did not demonstrate a significant effect on MTL dynamic network flexibility in our study. Although *APOE-ε4* allele remains one of the most robust genetic risk factors for AD in individuals of European descent, its role in AD pathology among individuals of African ancestry has been less well characterized. While previous research has linked *APOE-ε4* allele to hippocampal hyperactivation and prior learning deficits in this population (Barnes and Bennett, 2014; Murrell et al., 2006; Saeed et al., 2018; Sinha et al., 2018), our findings suggest that influence of *APOE-ε4* allele on MTL network dynamics may be weaker or more subtle than previously assumed. Future studies integrating multimodal imaging and ancestry-informative genetic markers will be important to disentangle the nuanced effects of *APOE-ε4* on neural network organization in this population.

When comparing the effects of “*ABCA7 rs115550680* risk allele-only” and “*APOE-ε4* allele-only” and “*ABCA7 rs115550680* × *APOE-ε4*” interaction model, our results reveal that *ABCA7 rs115550680* risk allele-only carriers exhibit significantly lower MTL dynamic network flexibility than *APOE-ε4* allele-only carriers and no effect on interaction model. Additionally, *ABCA7 rs115550680* risk allele-only carriers demonstrated significant hypertrophy in the left ERC compared to *APOE-ε4* allele-only carriers, suggesting the possibility of subregional structural remodeling, potentially driven by early compensatory functions. These findings highlight the potentially stronger influence of *ABCA7 rs115550680* risk allele on early neural dysfunction in African ancestry, underscoring its significance as a genetic risk factor for AD in this population. Taken together, these results highlight that *ABCA7 rs115550680* risk allele may exert a comparatively stronger influence on MTL flexibility than *APOE-ε4* allele in African Americans, though replication in independent cohorts is required.

Previous studies have demonstrated that the risk conferred by *APOE-ε4* allele varies across populations and is influenced by local ancestry at the *APOE* locus. Recent evidence also suggests that an African-origin haplotype within the *APOE* region may confer protection against AD

among *APOE-ε4* allele carriers (Nasciben et al., 2025). Together, these findings emphasize that the impact of genetic risk factors such as *APOE-ε4* and *ABCA7 rs115550680* can differ depending on ancestry background, highlighting the importance of considering local ancestry in genetic studies of AD. Our findings are consistent with previous reports that suggest *ABCA7 rs115550680* risk allele may exert a stronger influence than *APOE-ε4* allele in individuals of African ancestry (Reitz et al., 2013). By demonstrating the greater impact of *ABCA7 rs115550680* risk allele on MTL dynamic network flexibility, along with structural distinctions, our study emphasizes the need for a nuanced understanding of population-specific genetic vulnerabilities to AD.

Several limitations should be considered when interpreting these findings. *First*, the cross-sectional design limits causal inference and longitudinal studies are necessary to track changes in MTL network dynamics over time and examine how early disruptions in network flexibility may serve as predictive markers for the onset of cognitive decline and clinical AD. *Second*, the neuroimaging analysis focused solely on the MTL region, leaving open whether other brain regions show similar genetic effects. Future research to include broader brain networks could offer valuable insights into regional differences in the impact of genetic risk factors on neural network flexibility. In addition, our structural data were derived from T1-weighted imaging only, which limits the resolution needed to detect fine-grained subfield atrophy. Incorporating high-resolution T2-weighted imaging may improve sensitivity to early changes. *Third*, a relatively small sample size may have constrained the statistical power to detect subtle effects. Moreover, while we focused on genetic variants in *APOE-ε4* and *ABCA7 rs115550680*, other established genetic risk factors for AD were not considered. Future studies should aim to replicate these findings in larger, ancestrally diverse cohorts and explore polygenic influences on MTL network function across both structural and functional domains. *Fourth*, genetic analyses were restricted to a targeted panel of candidate variants. In particular, the functional 44-base-pair *ABCA7* frameshift deletion (*rs142076058*), which has been implicated in AD risk among African ancestry populations, was not directly genotyped. Instead, the present study focused on *ABCA7 rs115550680*, a well-established variant that is in strong linkage disequilibrium with *rs142076058* in African ancestry individuals and is widely used as a tagging marker in prior studies (Berg et al., 2019; De Roeck et al., 2019; Del-Aguila et al., 2015; Dib et al., 2021; Duchateau et al., 2024; Li et al., 2015; Reitz et al., 2013). Future studies incorporating sequencing-based approaches or direct genotyping of structural *ABCA7* variants will be important for clarifying underlying biological mechanisms. *Fifth*, because genome-wide genotype data were not available, population stratification could not be formally controlled using ancestry principal components. Although analyses were restricted to self-identified African American participants, residual within-group ancestry heterogeneity cannot be excluded and should be considered when interpreting the results. *Sixth*, participants were recruited through a community-engaged volunteer cohort, which may introduce self-selection bias, as individuals with heightened interest in brain health or a family history of dementia may be more likely to participate. In addition, the majority of participants were women, reflecting enrollment patterns commonly observed in community-based aging studies, which may limit generalizability to older African American men. *Finally*, given the exploratory and hypothesis-generating nature of this study, formal correction for multiple comparisons was not applied. Primary analyses were guided by a priori hypotheses focused on MTL network flexibility and selected MTL subregions based on prior literature (Brown et al., 2024; Chauveau et al., 2021; Das et al., 2013; Dickerson et al., 2009; Dickerson and Sperling, 2008; Hrybouski et al., 2023; Kang et al., 2024; Krasuski et al., 1998; Kukolja et al., 2010; Pasquini et al., 2016; Prieto et al., 2020; Sheldon and Levine, 2018; Soldan et al., 2015; Wolk et al., 2017). Accordingly, findings are interpreted cautiously as preliminary evidence, and replication in independent and longitudinal cohorts will be essential to confirm these associations.

In conclusion, our findings provide preliminary evidence that the *ABCA7 rs115550680* risk allele, but not *APOE-ε4* allele, is associated with reduced MTL flexibility and subregional hypertrophy in cognitively unimpaired older African Americans. These results suggest that *ABCA7 rs115550680* risk allele may exert a comparatively stronger influence on early neural dysfunction than *APOE-ε4* allele in this population. While the mechanisms remain to be clarified, the observed alterations could reflect transient, possibly compensatory or inflammatory remodeling processes. Importantly, our study underscores the need to consider ancestry-specific genetic risk factors when investigating early biomarkers of AD. Dynamic connectivity measures may offer a sensitive tool for detecting subtle genetic influences on brain function, but replication in larger, longitudinal, and ancestrally diverse cohorts will be critical to validate these observations and to inform strategies for early detection and precision-prevention in high-risk populations.
